ABSTRACT

The purpose of this study was twofold: to investigate to what extent characteristics of anchor tests may affect precision of item calibration, and to estimate to what extent precision of item calibration may be affected by removal of persons whose response patterns deviate from those normally expected from the Rasch one-parameter logistic model. Three characteristics of anchor tests were under consideration: the number of anchor items, and the range and average of difficulties of the anchor items. The data were taken from the nation-wide norming data of the Otis-Lennon School Ability Test, Form R, Intermediate Level. Anchor test characteristics did not show systematic effects on final calibration results. The removal of misfitting persons was detrimental to calibration results. Further studies are needed to clarify the effects of anchor test designs and person fit on linkings. (BW)

Presented at the 1984 Annual Meeting of the American Educational Research Association, New Orleans, La., April, 1984. The authors express their gratitude to the Psychological Corporation for making available to us the 1977 norming data of the Otis-Lennon School Ability Test. We are also grateful to R. Robert Rentz for providing computer programs and consultation.

INTRODUCTION

For decades, psychometricians have been striving to enhance objectivity, accuracy, and efficiency of mental measurement. The most important developments in recent years are probably the latent trait theory and its applications, particularly, computerized tailored testing. Availability of a large homogeneous item pool (of 200 or more items) is usually prerequisite for tailored testing and/or some other more advanced applications of the latent trait theory. Also required is that all the items in the pool be precisely calibrated on a single common scale. Since it is not feasible to administer a very long test to any single group of examinees, items for a pool are usually collected from several item sets which are calibrated on independent groups. (There are also some other factors that dictate collection of items from multiple item sets on independent groups, for instance, for updating an item pool or for constructing tests with comparability across time.) Unless equivalent groups are used in calibration, some conversion is usually needed to link item parameter estimates obtained from separate groups.

Linking two sets of separately calibrated items can be accomplished through either a common group of examinees who take both tests or through a set of common items (known as an anchor test) taken by different groups of examinees. Since usually it is inconvenient to use a common group of persons for linking, the anchor test approach becomes the primary means for linking and is the concern of the present study.

There are many psychometrical models subsumed to the latent trait theory. One of the more popular model is Rasch's one parameter logistic (1PL) model. Review of psychometric literature reveals that although 1PL model has attracted a large number of equating studies, only a few linking studies have been conducted. Equating and linking are symmetrical procedures and have some similarities; nevertheless, there are also important differences. Most of all, equating deals directly with accuracy of measured ability scores, whereas linking deals directly with precision of calibrated item estimates which eventually affect accuracy of measured ability scores.

In some equating studies, effect of length of anchor tests on accuracy of equated score was investigated, but no consistent results were reached. This is primarily due to lack of a good criterion for evaluation of equated scores. If the Monte Carlo method is used, the criterion problem is solved but the results may not conform to reality. A better solution is to employ several test forms to constitute a circular chain and through consecutive equating the initial test form will be finally equated to itself. Consistency of ability scores then becomes an evaluation criterion. Since it is extremely laborious, this approach is seldom used by researchers.

As far as linking is concerned, current knowledge about anchor test length and other characteristics is limited. From their item calibration experience using the classical test model, McBride and Weiss (1974) claimed that 40 to 60 anchor items may be needed to calibrate an item pool. Based on theoretical values of standard errors of item estimates, Wright considers a sample size

of 400 persons and an anchor test of 10 to 20 items as sufficient for most linking situations. Wright contends that ten anchor items may be adequate if the items are good (Wright, 1977).

While most linking studies dealt conceptually with linking problems, one empirical study (McKinley & Reckase, 1981) investigated effects of sample size and anchor test length on precision of item parameter estimates. There were three levels in test length-- 5, 15, and 25 items. Correlation between linked estimates and estimates obtained from the original total sample was used as an evaluation criterion. Obtained correlation values under all conditions were close to unity. Despite trivial differences among the correlations , results generally indicated the longer the anchor test and the larger the sample size, the better the precision. Only in one condition was the five-item anchor better than the fifteen-item anchor. The investigators thus thought a five-item anchor might be adequate, but a fifteen-item anchor was suggested.

However, the correlations used to evaluate calibration and linking results may be affected by distributions of item parameter estimates and does not necessarily reflect magnitude of errors introduced through estimation and linking processes. Moreover, factors other than size of samples and length of anchor tests also need to be identified and investigated to provide guidelines for construction of anchor tests for linking and guarantee that desired precision of item calibration can be reached.

In item calibration, misfit of an item to the Rasch model can be due to aberrant test-taking behavior of a few persons just as it can be due to a general flaw in the item itself. It is

conjectured that impact of irregular person responses can be serious when examinee sample size is small and that even large samples may not obliterate contaminating influence of irregular person responses (Wright & Stone, 1979, p. 82). Few previous studies deal with person fit problem and no one has investigated how removal of misfitting persons affects calibration of item pools.

The purpose of this study was twofold. One was to investigate to what extent characteristics of anchor tests may affect precision of item calibration. The other purpose was to estimate to what extent precision of item calibration may be affected by removal of persons whose response patterns deviate from what are normally expected from 1PL model. Three characteristics of anchor tests were under consideration, namely, test length, test width, and test height. These three characteristics correspond, respectively, to number of anchor items, range and average of difficulties of the anchor items (Wright & Stone, 1979, p. 133)

METHODS AND PROCEDURES

Design of the Study

The fundamentals of the design of this study can be perceived as similar to Angoff's (1971) Equating Design IV or Equating Design VI. The essentials of these designs are as follows:

Test (Form) X is administered to Group A; Test (Form) Y is administered to Group B. Tests (Forms) X and Y have a set of items in common (i.e., an anchor test). The anchor test is administered to both Group A and B and is used to adjust differences that exist between the two tests (forms).

In the present study, a nonanchor test was treated as if it were two different tests (i.e., analog of equating a test to itself). This kind of treatment was first used in equating research by Levine (1955). A number of more recent equating studies also used it (e.g., Green, 1980; Marco, Petersen, & Stewart, 1979; Pettie, 1981).

The present research was conducted in a fashion of an ex post facto experiment. Nonanchor test items calibrated with groups at two different grade levels were linked onto a base metric through 22 different anchor tests. The anchor tests differed from one another primarily in test height, width, and/or length. At the two grade levels, a pair of random samples of 1000 examinees each was drawn from a data base. The examinee sampling was replicated three times without replacement. Calibrating and linking with each pair of samples were performed under two different situations. In one situation, misfitting persons were not screened and the intact samples were used. In the other

situation, misfitting persons were detected and excluded from the groups. Since there were two situations, three replications of sample pairs, and 22 anchor tests, the total number of calibrations is 2 * 3 * 2 * 22 = 264. Final results of item calibration were evaluated in term of fidelity of item estimates.

Data Base

The data base used in the present study was taken from the nation-wide norming data of the Otis-Lennon School Ability Test(OLSAT), Form R, Intermediate level. The Intermediate level was designed for students in grades 6, 7, and 8. There are 80 items at this level in the Form R of the Otis-Lennon test. This form and level of the test was normed in fall, 1977. The sixth and the seventh graders' responses on the items were used in this research as the data base. There are responses from 11,776 sixth grade students and 11,020 seventh grade students in the data base (Otis & Lennon, 1979).

Preliminary Analysis

The sixth and the seventh grade students in the data base were treated as one population. All the items in the data base were calibrated with this population twice, once with the intact population and once with data of non-fitting persons deleted. These analyses yielded information regarding difficulty (DIFF), standard error of difficulty (STDERR), mean square fit (MSFIT), and slope of item response characteristic curve (i.e., discrimination) for each item. Table 1 and Table 2 show the item difficulty and related information from these calibrations. The

item difficulty values and the metric thus defined, as shown in Table 1, were taken as item parameters and as the base metric for subsequent analyses when all sample data were used. Table 2 shows similar information for subsequent analyses from which misfitting persons were removed from samples.

The population was then separated according to subjects' grade levels into two subpopulations. All the items in the data base were calibrated with each of the two subpopulations regardless of misfitting persons. Item difficulty values obtained from these two calibrations were plotted against each other to screen out possible outliers. An outlier was loosely defined as ,on the plot, a point that obviously deviated from the best fitted straight line of unit slope. The reason to screen and eliminate misfitting items with this particular method rather than employing slope and/or mean square fit values was that misfitting items could be better judged from such direct fitting results than from some indicators (Cf. Rentz, 1975). Slope and mean square fit values indicate item misfit in term of extent rather than type. Both of them lack definite criterion values for identifying misfitting items. Figure 1 presents the screening plot. No item was seen as an outlier; thus, all the 80 items in the data base were retained.

Construction of Anchor Tests and Nonanchor Tests

Construction of anchor tests and nonanchor tests was based on item parameters obtained from the calibration with the total population without excluding misfitting persons. Items were separated into two sets. One set contained 50 items and served

as an item pool for constructing anchor tests; the other set contained the remaining 30 items and was equally devided into three subsets for constructing nonanchor tests.

Anchor items were selected according to difficulty parameter values, such that difficulty values for 40 items spanned the range of - 2 to + 2 logits and were approximately equally spaced in that interval. Another 10 items were chosen approximately equally spread in the range of - 0.5 to 0.5 logits.

Twenty two anchor tests were constructed. One anchor test comprised all the anchor items. A second and a third anchor test consisted ,respectively, of the five and the ten best fitting anchor items, best fitting in the sense of having mean square fit values and slope index values near unity . The other 19 anchor tests differed from one another in the design of test height, width, and/or length. Test height, width, and length are synonyms, respectively, for average item difficulty, range of item diffculty, and number of items in a test . The 19 designed anchor tests centered around one of the following three height levels: - 1.0, 0.0, and 1.0 logits. At the - 1.0 and 1.0 height levels, there were 1.0 and 2.0 width levels. At the 1.0 width level, there were two length levels--lengths of five or ten items. At the 2.0 width level, there were three length levels--five, ten, and twenty items. At the 0.0 height level, there were three width levels— 1.0, 2.0 and 3.0. At each of these three width levels, test lengths were five, ten, or twenty items. Table 3 lists these specifications of the anchor tests and the actual height of each constructed anchor test.

Two nonanchor tests were constructed from the 30 items reserved for this purpose. One subtest of ten items was used in both nonanchor tests. These common items were combined with one of the other two ten-item subsets to form nonanchor tests for the 6th and 7th graders, respectively.

Table 4 lists the items assembled into each anchor test as well as into nonanchor tests. The numerals in the table are the same as actual item numbers in the Otis-Lennon School Ability Test.

Examinee Samples and Calibration Procedures

A pair of random samples of 1000 examinees each was drawn from the sixth and the seventh grade subpopulations. This examinee sampling process was replicated three times ,without replacement, resulting in three different sample pairs. Sampling examinees from the subpopulations was performed in two stages. In the first stage, random numbers were generated using a uniform random number function and the numbers were attached to examinees' data records. For each of the two subpopulations, three independent samples, each of a size slightly over 1000, were then produced by specifying three mutually exclusive ranges of the random numbers. In the second stage, exactly 1000 examinees' records were randomly taken from each sample. A computer software system, SAS, was utilized to accomplish the sampling of examinees (Cf. Ray, 1982; Council, 1980, p. 152).

Items in each of the two nonanchor tests, along with items in each of the 22 anchor tests, were calibrated with respective examinee samples in each sample pair. Nonanchor test items calibrated with lower grade level samples as well as the nonanchor

items calibrated with higher grade level samples were then placed, through different anchor tests, onto the base metric. The linked item estimates obtained from environments of different anchor tests and from each sample were compared with their item parameters. This was done for both intact-sample and excluding-misfitting-sample situations.

Exclusion of Misfitting Persons

Statistical procedures for identifying misfitting persons are illustrated in Wright and Stone (1979). According to them (p. 168), the person-fit statistic t is more or less normally distributed but with wider tails. They consider a rejection level of about 2.0 as conservative and 3.0 acceptable. The present study used t=2.5 as the critical value to detect and exclude misfitting persons.

Translation of Item Estimates

Conversion is needed to place item estimates from different data sets onto a common metric. Rationale and method for translating Rasch item difficulty estimates and/or examinee ability estimates from one test scale to another test scale have been described by Rentz and Bashaw (1975, 1977). More illustrations of linking together two sets of item estimates through an anchor test can be found in Mead (1981), Kreines and Mead (1979), and Wright and Stone (1979). With the Rasch model, whenever two separately calibrated tests both measure the same trait and both fit the model, the test scale defined for them will have the same units, but different origins (Rentz & Bashaw, 1977,

p. 162). To link together the two sets of items, usually, the scale of one of the tests is chosen to serve as a base metric and the other scale is to be adjusted. Adjustment is performed firstly by finding the difference (in log units) between the average of anchor item difficulties on the base metric and the average of anchor item difficulties on the test scale being adjusted. The difference is then used as an additive constant to translate the nonanchor item estimates from the scale being adjusted onto the base metric. Linking two sets of item estimates to a "preexisting" base metric is just the same as linking together two tests, except two, rather than one, sets of estimates need to be translated onto the particular base metric.

Evaluation Method and Criterion

Final results of item calibration (i.e., linked item difficulty estimates) were evaluated in term of fidelity of item estimates with an absolute criterion. Fidelity deals with discrepancies between each set of linked item estimates and the parameters. The criterion for evaluation was distance from an absolute value of zero. Distance is used here for values of fidelity discrepancy, irrespective of arithmetic signs.

Theoretically, discrepancy values should be close to zero if item calibration and linking can be done perfectly. Although perfect calibration actually never can be expected, distance from a value of zero can provide some useful information with regard to evaluating final calibration results. Descriptive statistics such as mean, standard deviation, minimum, and maximum of the distance values were calculated. In addition, means of

discrepancy values were also computed to indicate direction of possible bias.

Data Analysis

Estimations of item difficulty and related information were done by using a computer program called TRIAN; more exactly, June 1983 version of the TRIAN program was employed. The program was prepared by R. Robert Rentz to provide both traditional item analysis statistics and Rasch model analyses. The TRIAN program can perform person-fit analysis while estimating item and ability parameters. Unconditional maximum likelihood procedures of Wright and Panchapakesan (1969) and Wright and Mead (1976) have been adapted in the TRIAN program (Note 1). Programs written with SAS were used in computing translation constants, in linking difficulty estimates of the nonanchor test items to the base metric, and in performing the evaluation.

RESULTS

Sample Sizes

In Rasch calibration responses from any person who answers no item correctly (a zero test score) or all items correctly (a perfect test score) are not used. In the present study, total number of persons removed from any sample due to zero or perfect score in any calibration never exceeded seven. In the calibrations with removal of misfitting persons, the numbers of misfitting persons removed from samples varied from 34 to 132, but most were between 50 to 90.

Evaluation of Fidelity Discrepancy

An examination of means of discrepancy values does not reveal any systematic bias in the linked item estimates resulted from anchor test characteristics or person fit situations.

Evaluation of Fidelity Distance

Results of evaluation on fidelity distance are shown in Table 5 to Table 8. In these tables, characteristics of the anchor tests are the same as those in Table 3. Comparisons of the statistics across tests and samples for each grade and each situation do not show any systematic effect of anchor test characteristics on the final calibration results. Comparisons across situations for each grade seem to indicate that removal of misfitting persons makes calibration results slightly worse, if there are any differences, than no removal.

DISCUSSION

The fact that anchor test characteristics did not show systematic effects on final calibration results was considered to be probably due to one or both of the following two reasons:

A. The OLSAT data fit the Rasch model very well, and/or

B. There exists an inherent limitation on the precision of calibration that can be attained with the method used in the present study.

Theoretically, when data fit the model perfectly, linking results should be the same regardless of any difference in the characteristics of anchor tests. In other words, it should not matter what items constitute an anchor test if data fit the model perfectly.

The computer program TRIAN produces two item fit statistics: index of mean square fit and index of slope values. Overall fit of a set of data to the model can be evaluated through the values of these indices. However, due to the algorithm in the program, the values obtained for the index of slope from each calibration are very rough indicators of item fit. The mean square fit value for each item is a more accurate index but not a perfect one. The values of mean square fit for the OLSAT items indicate a good overall fit of the OLSAT data to the Rasch model.

An alternative approach to evaluate fit of data to the model is by examining plots of item difficulty values obtained from two subgroups of examinees. If there is a good fit then the points in a plot should fall along a 45 degree angle line. Again, this approach is merely a rough way of evaluation of fit. The fit of the OLSAT data to the Rasch model can be considered excellent if

we evaluate overall fit of the data to the model by way of the plot shown in Figure 1.

Through calibration and linking procedures, some errors are inevitably introduced into item parameter estimates. It has long been known that random sampling does not necessarily generate equivalent groups. From the replications of the samples in the present study, it was found that sample fluctuation may cause substantial errors even when sample size is as large as 1000. Also noticed was that sometimes estimates on individual items also fluctuate. The linking method used in this study makes adjustments on estimates for nonanchor items in each design circumstance by merely a single additive constant. While this simple method very accurately adjusted estimates for most items in most cases, it was not unexpected that it would have failed to perform well on some items in some cases. Results from an evaluation of fidelity discrepancy on individual items seemed to indicate that such failures were random events. Since the errors from these major sources were random and inevitable, systematic error brought about by anchor test characteristics, if any , may not be easily detectable. It should be noted that with empirical data it is very difficult to isolate each source of error. But for all practical purposes, the concern is usually the magnitude of total error associated with each item rather than the distinction of different error sources.

The fact that removal of misfitting persons seems detrimental to calibration results was attributed to one or both of the following two possible reasons:

A. Expansion in ranges of item estimates and scales defined by the estimates, and/or

B. Appropriateness of the person fit statistics.

In the present study it was found that item estimates and scales defined by the estimates were "stretched out" to about three tenths (in logit units) on both easy and hard ends when misfitting persons were excluded from calibrations. An examination of removed persons reveals that most misfitting persons were at the low ability end, but there were also some misfitting persons at the high ability end and some others in the middle. It is our conjecture that expansions in the item estimates (equivalently in the scales) allow somewhat larger errors to be introduced into the estimates.

Whether person fit statistics t is an appropriate measure for identification of misfitting persons is a question for which we do not have a ready answer at the present time. The person fit t index is a summary indicator of misfitting responses for each person. It is easy to use, but from a glance at some items misanswered by a number of misfitting persons, we suspect that the person fit t index may not be a valid way to screen irregular response patterns.

CONCLUSIONS AND SUGGESTIONS FOR FURTHER STUDIES

Based on the findings from this study, it seems two temporary conclusions can be drawn:

1. Linking can probably be done quite effectively over a wide range of anchor test designs, and

2. Removal of misfitting persons using person fit t index may work detrimentally.

Some further studies are certainly needed to better clarify the effects of anchor test designs and person fit on linkings. The OLSAT test used in this study is an unambiguously unidimensional test. The data seem to fit the model very well. For most achievement tests, dimensionality may not be so unambiguous and model-data fit may not be very good. In such cases whether the findings from this study can still hold needs to be investigated. After all, achievement testing is the area to which latent trait models are most likely to be applied. Whether there exists an inherent limitation on the precision that can be attained with the linking method used in this study can be investigated by applying the method to a variety of larger sample sizes. If errors obtained with some larger sample sizes approach nearly the same magnitude , a clear limitation can then be concluded. Different measures of person fit and their effects on linking also need to be more thoroughly studied before we can firmly declare who are misfitting persons and whether they should or should not be removed from calibration.
